Abstract

von Willebrand factor (VWF) plays an important role in ischemic stroke. However, the exact mechanism by which VWF mediates progression of ischemic stroke brain damage is not completely understood. Using flow cytometric analysis of single cell suspensions prepared from brain tissue and immunohistochemistry, we investigated the potential inflammatory mechanisms by which VWF contributes to ischemic stroke brain damage in a mouse model of cerebral ischemia/reperfusion injury. Twenty-four hours after stroke, flow cytometric analysis of brain tissue revealed that overall white blood cell recruitment in the ipsilesional brain hemisphere of VWF KO mice was 2 times lower than WT mice. More detailed analysis showed a specific reduction of proinflammatory monocytes, neutrophils and T-cells in the ischemic brain of VWF KO mice compared to WT mice. Interestingly, histological analysis revealed a substantial number of neutrophils and T-cells still within the microcirculation of the stroke brain, potentially contributing to the no-reflow phenomenon. Specific therapeutic targeting of the VWF A1 domain in WT mice resulted in reduced immune cell numbers in the affected brain and protected mice from ischemic stroke brain damage. More specifically, recruitment of proinflammatory monocytes was reduced two-fold, neutrophil recruitment was reduced five-fold and T-cell recruitment was reduced two-fold in mice treated with a VWF A1-targeting nanobody compared to mice receiving a control nanobody. In conclusion, our data identify a potential role for VWF in the recruitment of proinflammatory monocytes, neutrophils and T-cells to the ischemic brain via a mechanism that is mediated by its A1 domain.

Key words: von Willebrand factor, GPIb, thromboinflammation, ischemic stroke
Introduction

Ischemic stroke is caused by a blood clot occluding one or multiple cerebral arteries, often leading to irreversible brain damage. Unfortunately, treatment options are limited and not always successful. In 2015, stroke deaths accounted for 11.8% of total deaths worldwide, making stroke the second leading cause of death.\(^1\) The pathogenesis of ischemic stroke brain damage remains largely unclear and better understanding of the underlying mechanisms is crucial to meet the critical demand for improved stroke therapy.

Remarkably, while successful recanalization of the occluded blood vessel is necessary to alleviate ischemic stroke brain injury, it is often not sufficient. Indeed, there is no strict correlation between vessel recanalization and overall neurologic outcome 3-months after stroke.\(^2\) The reasons why efficient recanalization is not always associated with good clinical outcomes are unclear and most likely multifactorial. One key contributor is cerebral ischemia/reperfusion injury. The complex pathophysiology of cerebral ischemia/reperfusion injury includes both thrombotic and inflammatory pathways causing microvascular obstructions, increased blood brain barrier permeability, and overall neurological deterioration.\(^3\)

In recent years, the pathophysiological role of von Willebrand factor (VWF) in ischemic stroke has become apparent from both clinical and experimental studies.\(^4,5\) VWF is a large multimeric glycoprotein that recruits platelets at sites of vascular injury. Several case-control studies demonstrated increased VWF levels in ischemic stroke patients\(^6-11\) and high plasma levels of VWF were found to be an independent risk factor for ischemic stroke.\(^12\) Preclinical experiments have shown that mice lacking VWF show significantly reduced brain injury and better functional outcome in experimental models of cerebral ischemia/reperfusion injury.\(^13,14\) Remarkably, initial VWF-mediated platelet adhesion rather than subsequent platelet aggregation contributes to ischemic brain injury with a prominent role for the interaction between the VWF A1 domain and platelet glycoprotein (GP)Ibα.\(^15-19\) It is currently not known how exactly platelets and VWF contribute to stroke progression in a way that is not strictly related to platelet-thrombus formation. Most likely,
VWF-mediated acute inflammation also aggravates acute ischemic stroke brain injury\textsuperscript{20}, but the exact mechanisms of VWF-mediated inflammatory responses in stroke remain poorly understood.

In this study, we used flow cytometry and a unique nanobody that blocks the VWF A1 domain to investigate the precise role of VWF in the acute cerebral inflammatory response during stroke. We specifically found that neutrophils, monocytes and T-cells were recruited to the brain after stroke via a mechanism that involves the VWF A1 domain.
Methods

A detailed description of methods can be found in the online supplement.

Animals & Nanobodies

For this study, 10-week-old VWF knockout (KO)\textsuperscript{21} and littermate wild-type (WT) C57BL/6 mice were used. All animal experiments were approved by the local ethical committee (P050/2017 KU Leuven, Leuven, Belgium) and were performed following the ARRIVE guidelines (www.nc3rs.org.uk), including randomization of treatment and analysis blind to the treatment. Mice were treated with a well-characterized nanobody targeting the VWF A1 domain (KB-VWF-006 bv; 10 mg/kg) or a control nanobody (KB-VWF-004 bv; 10 mg/kg).\textsuperscript{22}

Cerebral ischemia and reperfusion injury model

Transient middle cerebral artery occlusion (tMCAO) was performed as described previously.\textsuperscript{17} Briefly, a standardized silicon rubber–coated 6.0 nylon monofilament (6021; Doccol Corp, Redlands, CA) was inserted via the right internal carotid artery to occlude the origin of the right MCA. The suture was left in situ for 60 minutes. Immediately after the start of reperfusion, nanobodies were administered intravenously.

Neurological tests

Twenty-four hours after induction of tMCAO; mice were subjected to the modified Bederson test\textsuperscript{23} and the grip test\textsuperscript{24} to assess global neurological and motor function respectively, as described.\textsuperscript{25}

Cerebral lesion quantification and assessment of bleeding

To measure cerebral infarct volumes, mice were euthanized 24 hours after induction of tMCAO. 2-mm-thick coronal brain sections were stained with 2% 2,3,5-triphenyl-tetrazolium chloride (TTC, Sigma-Aldrich, St Louis, MO) to visualize cerebral infarctions. The presence of cerebral hemorrhages was macroscopically assessed.
Flow cytometry

Twenty-four hours after stroke, mice were euthanized and perfused with 20mL of phosphate-buffered saline. Single-cell suspensions were made of the ischemic (ipsilateral) and non-ischemic (contralateral) hemispheres as previously described. Next, cells were incubated with appropriate antibody cocktails (Table 1) containing Fc-blocker. Live cells were stained with Live/Death violet cell viability staining (L34963; ThermoFisher; Waltham, MA) after which they were fixed and analyzed with a FACSVerse flow cytometer (BD, Franklin Lakes, NJ) and BD Facs Suite software.

Immunofluorescence

Twenty-four hours after stroke, mice were euthanized, and the brains were dissected. Nine µm thick sections were stained for the presence of neutrophils (rat anti-mouse Ly6G, 1/500, eBioscience, San Diego, CA), T-cells (Armenian hamster anti-mouse CD3e, 1/500, Biolegend, San Diego, CA), VWF (rabbit anti-human VWF, 1/1500, Dako, Santa Clara, CA) or platelets (rat anti-mouse GPIX, 1/100, emfret, Würzburg, Germany). For staining of the microvasculature, a lectin dye (FITC conjugated lectin from Lycopersicon esculentum, 1/500, Sigma-Aldrich) was used.

Statistical analysis

Statistical analysis was performed with Graph Pad Prism Version 8.1.2. Prior to statistical analysis, a D’ Agostino and Pearson normality test was used to check data distribution. One-way ANOVA with Dunnett’s post hoc test or a Mann-Whitney test was used for statistical comparison of infarct size and immune cell infiltration when applicable. In the case of non-parametric data (Bederson and grip-test score) a Kruskal-Wallis test with post hoc Dunn correction was performed. Infarct size is represented as mean ± standard deviation. Bederson and grip-test score are shown as scatter plot with median. Immune cell recruitment is shown as a min-max box plot, with the median.
Results

VWF-deficiency reduces immune cell recruitment to the brain after ischemic stroke

To examine the cerebral immune cell response mediated by VWF, we performed flow cytometric analysis of single cell suspensions prepared from brain tissue isolated from WT and VWF KO mice subjected to stroke. After stroke, mice were perfused, their brains harvested and subsequently divided into ipsilateral (affected by stroke) and contralateral (unaffected) hemispheres.

In agreement with previous reports, we observed significantly reduced cerebral infarcts in VWF KO mice, compared to WT mice (p < 0.01, Figure 1A). Twenty-four hours after stroke, the ipsilateral hemisphere showed an increased amount of infiltrated white blood cells (WBCs) compared to the contralateral hemisphere in both the WT (p < 0.005) and VWF KO mice (p < 0.05). However, averaged recruitment of WBC in the ipsilateral hemisphere of VWF KO mice was two-fold lower than in WT mice (5596 ± 1644 vs. 12435 ± 2083, respectively; p < 0.05, Figure 1B). Both the amount of myeloid and lymphoid white blood cells was significantly reduced in the brains of VWF KO mice compared to WT mice (p < 0.05, Figure 1C-D).

VWF deficiency leads to reduced recruitment of inflammatory monocytes, neutrophils and T-cells

To better determine which inflammatory cells were potentially recruited by VWF to the affected brain tissue during stroke, we used two antibody cocktails that allowed discrimination and quantification of recruited inflammatory monocytes, neutrophils, T-cells and CD3<sup>neg</sup> lymphocytes (B cells and NK cells) (Table 1).

As shown in figure 1E-H, all four subsets of immune cells were significantly increased in the ipsilateral brain of WT mice 24 hours after stroke, compared to the unaffected contralateral hemisphere. However, despite the presence of an infarct core in the affected ipsilateral hemisphere of VWF KO mice, the numbers of neutrophils and T-cells did not increase and remained similar to the baseline values of the contralateral hemisphere (Figure 1E and 1F). Hence, the absolute numbers of recruited neutrophils and T-cells was significantly higher in the ischemic brain of WT mice compared to VWF
KO mice (2017 ± 733 vs 512 ± 203, p < 0.05 and 974 ± 184 vs 244 ± 44, p < 0.01 respectively). These results suggest an important role for VWF in recruiting both neutrophils and T-cells to the affected brain tissue during ischemic stroke.

A similar, yet less outspoken, trend was observed for inflammatory monocytes (Figure 1G). In VWF KO mice, the ischemic hemisphere contained significantly more inflammatory monocytes than the unaffected hemisphere, but this was still significantly lower than the number of inflammatory monocytes that were recruited in the ischemic brain of WT mice (2466 ± 955 vs 6760 ± 1414; p < 0.05).

No differences regarding CD3<sup>−</sup> lymphocytes were observed between WT and VWF KO mice as similar numbers were recruited in the ischemic hemisphere of both groups (1162 ± 245 vs 585 ± 188 respectively, p > 0.05, Figure 1H). Leukocyte blood counts and circulating platelet-leukocyte complexes were similar between VWF KO and VWF WT mice 24 hours after stroke (data not shown).

**Visualization of VWF-mediated thromboinflammation in the ischemic stroke brain**

For visualization of VWF-mediated thromboinflammation, immunofluorescent staining of platelets and leukocytes was performed on brains obtained from VWF WT and KO mice 24 hours after stroke (Figures 2 and 3). In VWF KO mice, very few platelet accumulations were found within the ipsilateral brain (Figure 2A). In contrast, platelet/VWF-rich microthrombi were found frequently throughout the ipsilateral brain of VWF WT mice, underscoring the importance of VWF-mediated platelet adhesion in the ischemic stroke brain (Figure 2B-D). Platelet/VWF-rich microthrombi were absent in the contralateral hemisphere of both WT and VWF KO mice (data not shown).

Next, we visualized immune cell recruitment in VWF WT and KO mice. Since previous studies found no major role for monocytes<sup>27</sup>, but an important detrimental role for both T-cells<sup>28</sup> and neutrophils<sup>29</sup> in the acute phase of ischemic stroke, we focused on visualizing neutrophils and T-cells in the stroke brain. To stain the vasculature in both VWF WT and KO mice, a sensitive lectin staining of the endothelium was performed (Figure 3). Using a specific histological marker for neutrophils (Ly6G),
we observed that neutrophils were more frequently present within the ipsilateral side of the brain of VWF WT mice compared to VWF KO mice (Figure 3A-B). Since the smaller infarct sizes observed in VWF KO mice might bias neutrophil quantification by flow cytometry, we also quantified neutrophil recruitment in the ischemic infarct core in both VWF KO and WT mice by histology. Importantly, analysis of fixed areas of 1 mm$^2$ in the infarct core corroborated our flow cytometric data, arguing against a nonspecific effect related to smaller infarct sizes. Quantification of neutrophil recruitment to the infarct core revealed a two-fold reduction of neutrophil density in VWF KO brains compared to WT mice (Figure 3C). Intriguingly, neutrophils were frequently observed within the microcirculation (Figure 3A-B). To investigate this further, intra – and extravascular neutrophils were counted in brain sections of VWF WT mice. On average, 66 ± 4% of neutrophils were found within the vasculature of the ischemic hemisphere, while the remaining neutrophils were already extravasated (Figure 3D). A comparable observation was made when we stained for T-cells, which were also occasionally found within the microvasculature of VWF WT mice (Figure 3E). Due to the low number of T-cells within the ischemic brain, quantification of T-cells was not feasible. Lastly, T-cells were virtually absent in the ipsilateral brain hemisphere of VWF KO mice (Figure 3F), confirming our flow cytometric data.

**Inhibition of the VWF A1 domain reduces the recruitment of neutrophils, monocytes and T-cells and limits ischemic stroke brain injury**

Given the central role of the VWF A1 domain in cerebral ischemia/reperfusion injury, we next wanted to unravel its potential inflammatory contribution in ischemic stroke. To this end, we used a nanobody (KB-VWF-006bv) that specifically binds the VWF A1 domain, inhibiting its interaction with the platelet receptor GPIba. Intravenous treatment with 10mg/kg of the nanobody was started immediately after establishment of reperfusion. Mean residence time of the nanobody is 3.5 hours and this allows blocking of the VWF-A1 domain during the acute reperfusion phase. As a control, a nonspecific nanobody (KB-VWF-004bv) was administered. Twenty-four hours after stroke, mice treated with the anti-VWF A1 nanobody KB-VWF-006bv had significantly less ischemic stroke brain
damage compared to control-treated mice (Figure 4A and B). This translated in an improved motor score (Figure 4C) and neurological behavior (Figure 4D), although this difference was only statistically significant for the latter. Of note, no intracranial bleedings were observed in any of the mice treated with the VWF A1 nanobody. These data further corroborate the crucial involvement of the VWF-GPIbα axis in cerebral ischemia/reperfusion injury.15-17,19

Targeting the VWF A1 domain also significantly reduced inflammatory cell recruitment to the ischemic brain (Figure 5). Indeed, similar to our results in VWF KO mice, flow cytometric analysis revealed that inhibition of VWF A1 also leads to a 2-fold reduction of immune cell recruitment in the brains of treated mice compared to control mice (7095 ± 2550 vs 16310 ± 3980; p < 0.005; Fig. 5A).

Both myeloid (5195 ± 2259 vs 11978 ± 3322; p < 0.05; Fig. 5B) and lymphoid WBCs (1529 ± 269 vs 3017 ± 514; p < 0.05; Fig. 5C) were reduced in the ipsilateral hemispheres of VWF A1 nanobody treated mice. Specifically, inhibition of the VWF A1 domain reduced the amount of infiltrated inflammatory monocytes (3726 ± 1824 vs 8266 ± 2651; p < 0.05; Fig. 5D), neutrophils (304 ± 94 vs 1557 ± 317; p < 0.0005; Fig. 5E) and T-cells (487 ± 93 vs 1111 ± 248; p < 0.05; Fig. 5F) in the ipsilateral hemisphere of the brain, 24 hours after stroke. These data suggest that the inflammatory effect of VWF in ischemic stroke is mediated through the VWF A1 domain.
Discussion

As the main finding from this study, we report that VWF mediates an inflammatory response during cerebral ischemia/reperfusion via the recruitment of inflammatory monocytes, neutrophils and T-cells, through a mechanism that is dependent on the VWF A1 domain. Blocking of the A1 domain reduced the inflammatory response and improved stroke outcome.

Current ischemic stroke treatment is aimed at achieving reperfusion of the ischemic brain as soon as possible. When thrombolysis or thrombectomy is initiated, an unsalvageable infarct core often already exists. Reperfusion therapy is therefore aimed at salvaging the penumbra to limit further ischemic brain damage. Unfortunately, rescue of the perfused salvageable penumbra is not always achieved, which has led to the concept of cerebral ischemia/reperfusion injury. In recent years, VWF has emerged as an important mediator of cerebral ischemia/reperfusion injury. We and others reported that absence of VWF protected mice from ischemic stroke brain injury, without increasing the risk for cerebral bleeding. Intriguingly, the detrimental role of VWF in the ischemic brain appears to be distinctive of its role in hemostasis. Whereas hemostatic thrombus formation requires both platelet adhesion and platelet aggregation, the latter does not seem to play a major role in reperfusion injury after ischemic stroke. Besides thrombotic events, ischemic stroke is also characterized by a strong inflammatory response that occurs in the brain after reperfusion. Since VWF is a known modulator of inflammation, a thromboinflammatory role for VWF in the ischemic stroke brain was proposed. Yet, the inflammatory mechanisms by which VWF mediates reperfusion injury in the ischemic stroke brain remained poorly understood. Via flow cytometric analysis of single cell suspensions prepared from brain tissue from VWF KO and WT mice and histology experiments, we found that the acute immune response in the brain after stroke was greatly reduced in the absence of VWF. These results further corroborate the notion that VWF contributes to cerebral inflammation in stroke. In agreement with Khan et al, we found that neutrophil recruitment to the ischemic stroke brain was significantly reduced in VWF deficient mice compared to WT mice. Interestingly, we additionally identified a 2-fold decrease in the recruitment of inflammatory
monocytes and a 4-fold decrease in the recruitment of T-cells to the ischemic stroke brain of VWF deficient mice. Importantly, not only the overall number but also the density of neutrophils in the affected brain tissue was reduced. Furthermore, there is no direct link between the reduction in infarct size (2-fold) and the reduction of all subsets of leukocytes (2 to 5-fold). Together, these observations go against a potential nonspecific effect due to smaller infarct volumes.

Ischemic stroke induces an extensive inflammatory response, with various types of immune cells transmigrating over the activated endothelium to invade the damaged brain. The key steps mediating the initial phase of leukocyte-mediated stroke brain damage are not yet fully resolved. During cerebral ischemia, the brain endothelium becomes rapidly activated, resulting in the up-regulation of cell adhesion molecules. Together with transient disruption of the BBB, this allows entry of leukocytes in the brain. Our results now suggest that VWF is an important molecule involved in the initial recruitment of inflammatory monocytes, T-cells and neutrophils leading to reperfusion injury. The potential role of monocytes in the acute phase of ischemic stroke is not clear but interactions between monocytes and VWF-platelet complexes have been shown to contribute to monocyte diapedesis in vitro. Both neutrophils and T-cells have been found to cause cerebral ischemia/reperfusion injury by obstructing the microcirculation, contributing to the no-reflow phenomenon. Interestingly, we observed a significant amount of neutrophils and T-cells within the microvasculature of WT mice during the early phase after stroke. Whether these cells are in the process of extravasating or really plugging the microcirculation is hard to ascertain from our current study. Together with VWF/platelet aggregates, these intravascular immune cells can occlude brain capillaries and impair microcirculatory reperfusion. Our observations are in line with other studies reporting on neutrophil recruitment to the brain after stroke. Indeed, neutrophils have been found trapped in the cerebral microcirculation in both murine and baboon stroke models. Importantly, also in human stroke patients, intravascular neutrophil accumulation has been observed in post mortem brain tissue. Similarly, regulatory T-cells were found to increase cerebral thrombus formation, impair cerebral reperfusion and caused overall microvascular dysfunction in the acute
reperfusion phase in a murine stroke model.\textsuperscript{44} Accordingly, depletion of neutrophils or T-cells in the acute phase of ischemic stroke has a protective effect.\textsuperscript{28,35,44-46} Our results now identify VWF as a key adhesion molecule that could be implicated in the recruitment of these immune cells, most likely via a platelet dependent mechanisms, potentially triggering microvascular obstructions in the reperfused ischemic stroke brain.

A key finding of this study is that we could pinpoint the pathogenic contribution of VWF to its A1 domain using a nanobody that specifically targets the platelet GPIbα binding site in the VWF A1 domain.\textsuperscript{22} Indeed, anti-VWF A1 nanobody treatment resulted in a similar reduction of leukocyte recruitment as VWF deficient animals (Supplemental table 1). This nanobody was previously shown to reduce overall leukocyte recruitment in a model of immune complex-mediated vasculitis and a model of irritant contact dermatitis, suggesting that the pro-inflammatory properties of the VWF A1 domain can play an important role in several settings.\textsuperscript{22} Pendu et al. have previously demonstrated that VWF, potentially via the A1 domain, was able to directly interact with PSGL-1 and several β2 integrins on leukocytes.\textsuperscript{47} PSGL-1 and β2 integrins are present on monocytes, neutrophils and T-cells and their interaction with VWF is one possible mechanism by which VWF can recruit leukocytes in the ischemic brain. Another mechanism by which VWF most likely recruits leukocytes involves platelets that are bound to the VWF A1 domain via their GPIbα receptor. Platelets can subsequently bind leukocytes through well-established interactions.\textsuperscript{48} This VWF-platelet mediated leukocyte recruitment was previously presented in an elegant study by Petri and colleagues.\textsuperscript{49} They observed that peritoneal inflammation triggered the release and cell surface deposition of endothelial VWF which allowed platelets to adhere to the endothelium via GPIbα and subsequently recruit leukocytes. Blocking of VWF or depleting platelets had an equally strong anti-inflammatory effect in their model, highlighting the inflammatory role of VWF-associated platelets. A similar course of events is most likely also occurring in the ischemic brain. The detrimental interaction between VWF and platelets has already been extensively studied in the setting of stroke.\textsuperscript{15,17,19} Our results again highlight the importance of the inflammatory component of VWF-GPIbα interaction in the ischemic stroke brain.
Furthermore, our findings corroborate the observations of Schuhmann et al, who after inhibition of platelet GPIbα, also observed an attenuated inflammatory response, which protected mice from cerebral ischemia-reperfusion injury.50

Our study has some limitations that need to be addressed. First, all outcomes were measured at 24 hours after ischemic stroke. This timepoint was chosen to specifically investigate the early, acute inflammatory response after stroke. Nevertheless, previously, it was shown that leukocyte infiltration peaks at 72 hours after ischemic stroke in mice.51 It would be interesting to investigate VWF-mediated inflammatory responses at later timepoints or even during initial ischemia. Second, the set-up of our study did not allow identification of the specific interactions that mediate leukocyte-platelet or leukocyte-VWF binding in the setting of ischemic stroke. Specific inhibitors of platelet-leukocyte or VWF-leukocyte interactions would be needed to further elucidate the specific leukocyte interactions. Lastly, histology or flow cytometric analysis of brain tissue will not perfectly reflect the dynamic inflammatory processes ongoing in the ischemic stroke brain. Future studies are needed to visualize VWF-platelet-leukocyte interaction in vivo by for example intravital microscopy.

In conclusion, we found that VWF is involved in the recruitment of inflammatory monocytes, neutrophils and T-cells to the ischemic brain via its A1 domain. Inhibition of VWF-mediated thromboinflammation, for example by blocking the VWF A1-GPIbα interaction, or by cleaving VWF with ADAMTS13, could become promising treatment strategies for the prevention of cerebral ischemia/reperfusion injury.

Quantification of the number of neutrophils/mm² in the infarct core of WT and VWF KO mice. (n = 3) Data is represented as mean ± standard deviation. D. The number of neutrophils within and outside the vasculature (n = 3). Data is represented as mean ± standard deviation. E and F. T-cells were stained with a marker for CD3 (red) and blood vessels with a lectin staining (green). T-cells are marked with a *. Scale bars are 20μm. Images are representative for n = 3 per genotype.

Figure 4: Inhibition of the VWF-A1 domain protects mice from acute ischemic stroke. Transient focal cerebral ischemia was induced by 60 minutes occlusion of the right middle cerebral artery (tMCAO), followed by 23 hours of reperfusion. Immediately at the start of reperfusion, mice were intravenously treated with 10 mg/kg of either control (KB-VWF-004 bv) or inhibitory anti-VWF A1 nanobody (KB-VWF-006 bv). A. Edema-corrected brain infarct volumes were quantified by planimetric analysis 24 hours after stroke. B. Representative TTC staining of 3 consecutive brain sections. C. Motor function was examined using the grip test. D. Neurological outcome 24 h after stroke was assessed using the Bederson test. Data are represented as scatter plots showing all data points and the median value, except for infarct size which is shown as mean ± standard deviation. *, p<0.05; **, p<0.01. (n = 10-11)

Figure 5: The VWF-A1 domain recruits monocytes, neutrophils and T-cells to the brain after acute ischemic stroke. Transient focal cerebral ischemia was induced by 60 minutes occlusion of the right middle cerebral artery (tMCAO), followed by 23 hours of reperfusion. Immediately at the start of reperfusion, mice were intravenously treated with 10 mg/kg of either control (KB-VWF-004 bv) or inhibitory anti-VWF A1 nanobody (KB-VWF-006 bv). Twenty-four hours after tMCAO, recruitment of
specific subsets of WBC to each hemisphere was determined by flow cytometry. **A. White blood cells (CD45^{high}).** **B. Myeloid white blood cells (CD45^{high}; CD11b^+).** **C. Lymphoid white blood cells (CD45^{high}; CD11b^-; CD11c^-).** **D. Inflammatory Monocytes (CD45^{high}; CD11b^+; Ly6C^-; Ly6G^-).** **E. Neutrophils (CD45^{high}; CD11b^+; Ly6G^+).** **F. T-cells (CD45^{high}; CD11b^-; CD11c^-; CD3e^+).** **G. CD3^- lymphocytes (CD45^{high}; CD11b^-; CD11c^-; CD3e^-).** * p < 0.05; **, p<0.01; ***, p < 0.005; ****, p<0.001. (n = 10-11)
The von Willebrand Factor A1 domain mediates thromboinflammation, aggravating ischemic stroke outcome in mice

Running head: VWF-mediated thromboinflammation in stroke

Supplemental Materials and Methods

Animals & Nanobodies

For this study, 10-week-old VWF knockout (KO) and littermate wild-type (WT) C57BL/6 mice were used. All animal experiments were approved by the local ethical committee (P050/2017 KU Leuven, Leuven, Belgium) and were performed following the ARRIVE guidelines (www.nc3rs.org.uk), including randomization of treatment as well as surgery and analysis blind to the treatment. Mice were treated with a well-characterized nanobody targeting the VWF A1 domain (KB-VWF-006 bv; 10 mg/kg) or a control nanobody (KB-VWF-004 bv; 10 mg/kg).

Cerebral ischemia and reperfusion injury model

Transient middle cerebral artery occlusion (tMCAO) was performed as described previously. Anesthesia was induced and maintained by inhalation of 5% and 2% isoflurane in medical oxygen respectively. After a midline incision in the neck, the proximal common carotid artery and the external carotid artery were ligated and a standardized silicon rubber–coated 6.0 nylon monofilament (6021; Doccol Corp, Redlands, CA) was inserted and advanced via the right internal carotid artery to occlude the origin of the right MCA. The intraluminal suture was left in situ for 60 minutes. Next, animals were re-anesthetized, and the occluding monofilament was withdrawn to allow reperfusion. Surgery time did not exceed 10 minutes per animal. Immediately after the start of reperfusion, nanobodies were administered via intravenous injection.

The following criteria excluded mice from endpoint analyses: death within 24 hours after tMCAO or the occurrence of surgical complications. Of the 55 mice subjected to tMCAO, four were excluded because they died during the time of the experiment and six mice were excluded due to surgical complications. No difference in mortality rate was observed between the different experimental groups. Researchers and operators were blinded to the experimental groups for all readout parameters.
Neurological tests
Twenty-four hours after induction of tMCAO; mice were subjected to the modified Bederson test and the grip test to assess global neurological and motor function respectively, as described.

Cerebral lesion quantification and assessment of bleeding
To measure cerebral infarct volumes, mice were euthanized 24 hours after induction of tMCAO. Brains were quickly isolated and cut into 2-mm-thick coronal sections using a mouse brain slice matrix. The slices were stained with 2% 2,3,5-triphenyl-tetrazolium chloride (TTC, Sigma-Aldrich, St Louis, MO) to distinguish healthy tissue from unstained infarctions. Stained slices were photographed with a digital Nikon D70 camera and infarct areas (white) were measured using Image J software (National Institutes of Health, Bethesda, MD) by an operator blinded to the experimental conditions. Edema corrected infarct sizes were calculated by use of the following equation: \( V_{\text{corrected}} = V_{\text{uncorrected}} \times \left(1 - \frac{V_i - V_c}{V_c}\right) \) where \( V_i - V_c \) represents the volume difference between the ischemic hemisphere and the contralateral hemisphere and \( \frac{V_i - V_c}{V_c} \) expresses this difference as a fraction of the contralateral hemisphere. The presence of cerebral hemorrhages was macroscopically assessed upon brain isolation as well as via careful visual analysis of the coronal brain sections after cutting.

Flow cytometry
Twenty-four hours after stroke, mice were euthanized and perfused with 20mL of phosphate-buffered saline. After dissecting the brain and removing the cerebellum, the two hemispheres were separated into the right ischemic (ipsilateral) and left non-ischemic (contralateral) one. The hemispheres were mechanically disrupted using a scalpel and subsequently incubated for 30 minutes at 37°C with a digestion buffer (2.5 mg/mL collagenase D (17104-019, Invitrogen, Carlsbad, CA), 5 U/mL DNase I (EN0521, Thermo
Scientific, Waltham, MA) in RPMI 1640 + 10% inactivated fetal calf serum (FCS, 10500-064, Invitrogen)) and pressed through a cell strainer (40 μm). Next, cells were separated from myelin and debris by Percoll (17-0891-02, GE Healthcare, Chicago, IL) gradient centrifugation and incubated with appropriate antibody cocktails (described below) containing an Fc-blocker (30 minutes at room temperature) in PBS + 5% FBS. Live cells were stained with Live/Death violet cell viability staining (L34963; ThermoFisher; Waltham, MA) after which they were fixed in 200 μL 0.5% paraformaldehyde and analyzed with a FACSVerse flow cytometer (BD, Franklin Lakes, NJ) and BD Facs Suite software. Sample acquisition was performed until 10000 live cells were analyzed, and thereafter the total cell count per hemisphere was calculated.

Two antibody cocktails were used to identify different leukocyte subsets (Table 1). The first antibody cocktail allowed determination of overall leukocyte (CD45<sup>high</sup>), myeloid leukocyte (CD45<sup>high</sup> and CD11b<sup>+</sup>), neutrophil (CD45<sup>high</sup>, CD11b<sup>+</sup> and Ly6G<sup>+</sup>) and monocyte (CD45<sup>high</sup>, CD11b<sup>+</sup>, Ly6C<sup>+</sup> and Ly6G<sup>+</sup>) count. With the second antibody cocktail, lymphocyte (CD45<sup>high</sup>, CD11b<sup>−</sup> and CD11c<sup>−</sup>), T-cell (CD45<sup>high</sup>, CD11b<sup>−</sup>, CD11c<sup>−</sup>, CD3e<sup>+</sup>) and CD3<sup>neg</sup> lymphocytes (CD45<sup>high</sup>, CD11b<sup>−</sup>, CD11c<sup>−</sup>, CD3e<sup>−</sup>) count were determined.

**Immunofluorescence**

Twenty-four hours after stroke, mice were euthanized and the brains were dissected. Brains were cut into 2mm-thick coronal sections, immediately placed in O.C.T. compound and frozen in liquid nitrogen for sectioning. Nine μm thick sections were stained for the presence of neutrophils (rat anti-mouse Ly6G, 1/500, eBioscience, San Diego, CA), T-cells (Armenian hamster anti-mouse CD3e, 1/500, Biolegend, San Diego, CA), VWF (rabbit anti-human VWF, 1/1500, Dako, Santa Clara, CA) or platelets (rat anti-mouse GPIX, 1/100, emfret, Würzburg, Germany). For staining of the microvasculature, a lectin dye (FITC conjugated lectin from Lycopersicon esculentum, 1/500, Sigma-Aldrich) was used. Briefly, sections were washed in TBS; blocked with 1% normal rat, Armenian hamster, or rabbit serum; 3% BSA and 0.1% Triton X-100 in TBS for one hour and incubated overnight at 4°C with various combinations of primary antibodies. After
washing, slides were incubated for one hour at room temperature with the corresponding secondary antibodies: Alexa Fluor 647 goat anti-Armenian hamster IgG (1,5 µg/ml, 405510; BioLegend), Alexa Fluor Plus 555 goat anti-rat IgG (1,5 µg/ml, A21434, Invitrogen) or Alexa Fluor 647 donkey anti-sheep IgG (1,5 µg/ml, A21488, Invitrogen). Prolong Gold Antifade mounting solution with 4,6-diamidino-2-phenylindole (DAPI; Invitrogen) was used to stain DNA. As negative control, the primary antibody was omitted. Images were acquired using a laser scanning confocal microscope (LSM710, Zeiss, Oberkochen, Germany). Images were processed by Zen 2012 (blue edition, version 2.3, Zeiss) software. Neutrophils were counted in 6 brain sections per mouse for 3 WT mice, for quantification of their localization.

**Statistical analysis**

Statistical analysis was performed with Graph Pad Prism Version 8.1.2. The number of experimental animals in each group was based on power calculations with infarct volume as primary parameter and with mean differences and standard deviations taken from available data from the same tMCAO model (power of 80% and α of 0.05). Prior to statistical analysis, a D' Agostino and Pearson normality test was used to check data distribution. One-way ANOVA with Dunnett’s post hoc test or a Mann-Whitney test was used for statistical comparison of infarct size and immune cell infiltration when applicable. In the case of non-parametric data (Bederson and grip-test score) a Kruskal–Wallis test with post hoc Dunn correction was performed. Infarct size is represented as mean ± standard deviation. Bederson and grip-test score are shown as scatter plot with median. Immune cell recruitment is shown as a min-max box plot, with the median.
Supplemental Table 1. Comparison of effect of genetic VWF deficiency or anti-VWF A1 nanobody treatment on cerebral leukocyte recruitment after stroke. Data is represented as mean ± standard error of the mean; * p < 0.05; **, p<0.01; ***: p < 0.005.
