Publisher's Disclaimer.
E-publishing ahead of print is increasingly important for the rapid dissemination of science. Haematologica is, therefore, E-publishing PDF files of an early version of manuscripts that have completed a regular peer review and have been accepted for publication. E-publishing of this PDF file has been approved by the authors. After having E-published Ahead of Print, manuscripts will then undergo technical and English editing, typesetting, proof correction and be presented for the authors' final approval; the final version of the manuscript will then appear in a regular issue of the journal. All legal disclaimers that apply to the journal also pertain to this production process.
A novel index to evaluate ineffective erythropoiesis in hematological diseases offers insights into sickle cell disease

Running title: Novel index to evaluate ineffective erythropoiesis

Corresponding Author: Dr Sara El Hoss, Molecular Haematology, Comprehensive Cancer Centre, School of Cancer & Pharmaceutical Sciences, Rayne Institute, King’s College London, 123 Coldharbour Lane, SE5 9NU, London. Email: sara.el_hoss@kcl.ac.uk

Acknowledgments

We would like to thank the patients involved in this study and the medical staff of KCH for taking care of the patients. We also thank the members of the Molecular Haematology research lab at King’s College London for their support during this work.

Author Contributions

JB collected data, analysed, wrote and edited the manuscript. SEH analysed data, wrote and edited the manuscript. JS contributed to the design of the study, interpretation of data and wrote and edited the manuscript. DR designed the study, wrote and edited the manuscript.

Disclosure of Conflicts of Interest

The authors declare no conflict of interest
Ineffective erythropoiesis (IE) is an important pathological factor in many types of anemia, including beta-thalassemia and myelodysplasia and more recently described in sickle cell disease (SCD). We have evaluated a novel index of ineffective erythropoiesis (IoIE) as a way of quantitating IE and facilitating its comparison between patients, conditions, and the effects of treatments. We calculated IoIE by dividing the plasma concentration of soluble transferrin receptor (sTfR, nmol/l) (proportionate to the volume of erythroid tissue) by the absolute reticulocyte count (ARC, x10⁹/l) (effective erythroid output from the bone marrow). The upper limit of normal IoIE was calculated at 0.28, using the established normal ranges of sTfR and ARC, and confirmed using control samples. We studied 414 SCD patients and show that IE is a feature of patients with HbSS (median IoIE 0.37), but not HbSC (median IoIE 0.27). We validated IoIE as a measure of IE in a cohort of 44 patients with HbE-beta thalassemia patients, a condition in which IE is known to play a major part, and as expected found high levels (median IoIE 1.46). Within the HbSS cohort, we find higher HbF levels associate with reduced IE and that transfusion reduces IE, whereas hydroxyurea (HU) treatment appears to lead to increased IE. This index is a simple and meaningful measure of IE, showing that it is clinically important in SCD, and suggesting novel therapeutic approaches.
Ineffective erythropoiesis (IE) is the abnormal differentiation of erythroid progenitors, with an expanded progenitor compartment, increased erythroblast destruction and a relative paucity of reticulocytes produced compared to the volume of the erythron\(^1\). IE is well described in beta-thalassemia, but less so in sickle cell disease (SCD), where anaemia is generally attributed to hemolysis\(^2\). There is, however, evidence of dysfunctional erythroid differentiation in SCD. Erythroblasts isolated from the bone marrow of SCD patients sickle under hypoxic conditions\(^3\), whilst analysis of chimeric hematopoiesis in non-myeloablative transplanted SCD patients demonstrated a survival advantage of the donor erythroid progenitor cells\(^4\). More recently, high levels of apoptosis between the polychromatic and orthochromatic stages were identified, with fetal hemoglobin (HbF) being a key protective factor against this\(^5\).

Quantitation of IE in patients would facilitate its study in SCD and other anemias, and allow the assessment of novel treatments. Transferrin receptor (CD71) is a membrane protein expressed during erythropoiesis. It is also released into the circulation, with its serum concentration shown to be proportional to the mass of erythropoietic tissue\(^6,7\). Soluble transferrin receptor (sTfR) levels are elevated in SCD reflecting an increased erythropoietic drive, but show no correlation with disease severity\(^8\). We propose a meaningful representation of IE which can be determined by measuring the ratio of the mass of erythropoietic tissue (sTfR) to the erythroid output from the marrow (ARC), analogous to the way the reticulocyte percent correlates with the rate of hemolysis\(^9\). Where IE is occurring, the erythron mass will be large, with higher sTfR levels, whilst the relative output of reticulocytes (ARC) will be lower, and the ratio will be higher. We refer to this ratio as the Index of Ineffective Erythropoiesis (IoIE), and explore its significance in patients with SCD. We also validate this index in a cohort of patients with non-transfusion dependent HbE/beta-
thalassaemia, in which IE is known to predominate and in a control group with no iron deficiency, no hematological disease or other condition which might impact erythropoiesis.

All patients with SCD were recruited from King’s College Hospital, London UK. Written informed consent was obtained through three approved study protocols (LREC 01-083, 07/H0606/165, and 12/LO/1610). Patient electronic records were reviewed from 2008 to present for all measurements of sTfR and ARC taken on the same day in the outpatient setting. Contemporaneous Hemoglobin (Hb) and HbF levels were also recorded and note made of disease modifying therapy: ongoing regular blood transfusion within 90 days, HU use, or neither. Measurements were excluded if there was evidence of iron deficiency (serum ferritin <30 micrograms/L), or if the patient was younger than 16 years of age at time of sampling. Data from a previous study of patients with HbE/β thalassaemia were collected and analysed to validate the index. Data from 22 control samples was also analysed; these were samples from adult patients taken for clinical reasons, without iron deficiency or any other condition known to affect erythropoiesis or red cell survival.

Determination of alpha thalassaemia, G6PD, and g(HbF), a composite measure of the major genetic determinants of HbF, in this cohort are described elsewhere. sTfR was measured using an ELISA (R&D Systems, Minneapolis, USA) and reticulocytes were measured using automated counting based on RNA staining (Siemens Healthcare, Erlangen, Germany).

Index of ineffective erythropoiesis (IoIE) was calculated by dividing sTfR (nmol/l) by the ARC (x10⁹/l). We defined the limit of the normal range by applying this formula to the well-established upper limit of the normal ranges of sTfR (28.1 nmol/L) and ARC (100x10⁹/L) giving a value of 0.28, and validated this with control samples. Where multiple measurements were available, averages were taken. Statistical analyses were performed with GraphPad Prism (version 9). The data were analysed using Mann-Whitney unpaired test and Wilcoxon paired test, as indicated. Correlations were performed using Spearman correlation.
There were 22 controls, 182 patients with HbSS, 87 with HbSC and 12 with HbS/beta-thalassemia without disease modifying therapy, with comparable age range and sex ratio (Table 1). As expected, HbSS patients had significantly lower Hb levels and higher ARC, as compared to patients with either HbSC or HbS/beta\textsuperscript{+}-thalassemia (Figure 1A), and sTfR levels are significantly higher in the HbSS genotype (Figure 1B). There was a strong correlation between ARC and sTfR levels. ($r=0.3773, p<0.0001$, Figure 1D).

The IoIE in the non-treated HbSS group was elevated at 0.37 as compared to the control group (0.209) suggesting some degree of IE. This was significantly less than in the validation cohort of 23 non-transfused patients with HbE/beta-thalassaemia, with a median IoIE of 1.46 (Table 1, Figure 1C). By contrast, in the HbSC group the IoIE, 0.27, fell within normal range though remaining slightly higher than the control group ($p=0.0174$). The difference between HbSS and HbSC groups was statistically significant ($p<0.0001$). Although the numbers were small, the IoIE in the HbS/beta\textsuperscript{+}-thalassaemia group was higher (0.35) than that of HbSC and significantly higher than the control ($p=0.0015$), despite similar levels of anaemia and disease severity as compared to HbSC (Figure 1C).

We assessed factors known to influence disease severity in HbSS with the IoIE. We found a significant negative correlation with Hb ($r=-0.32, p=6\times10^{-6}$), (Figure 1E), and HbF ($r=-0.20, p=0.02$) (Figure 1F), but no association with G6PD status, ($p=0.062$), deletional alpha thalassaemia ($p=0.26$), or g(HbF) ($r=0.02, p=0.82$). These findings, together with previous work implicating HbF levels in IE\textsuperscript{5}, may suggest that increased gamma globin synthesis in erythroblasts reduces IE in SCD and contributes to higher Hb levels by improving erythropoiesis, as well as prolonging red cell survival.

HU and blood transfusion therapy are the two main treatment options in patients with SCD. We evaluated the IoIE in 58 regularly transfused and 50 HU-treated patients. The transfused patients were on long-term regular transfusions, mostly because of cerebrovascular disease to
keep the HbS level below 30%. The patients on HU had all been taking it for at least six months, and were treated according to clinical response rather than at maximum tolerated dose. In each of these groups, the measurements of Hb, HbF, and ARC differed from baseline in accordance with previously published data (Table 1)\textsuperscript{13,14}, whilst sTfR levels decreased in both groups (Figure 1H). By contrast, the IoIE was significantly lower with transfusions (IoIE=0.26, \( p=7.2\times10^{-6} \)), but significantly higher with HU treatment (IoIE=0.42, \( p=0.042 \)) (Figure 1I). We validated these findings in 17 patients for whom both baseline and post-transfusion measurements were available (paired t-test, \( p=0.019 \)) (Figure 1L) and 20 patients for whom both baseline and HU treated measurements were available (paired t-test, \( p=0.004 \)) and confirmed that IoIE actively increased with HU (Figure 1J) and decreased with transfusion (Figure 1K). There was no correlation between HbF and IoIE in patients on HU (\( P=0.072 \)), although numbers were small.

The improvement in IoIE seen in patients on blood transfusions contrasts to that seen with regular blood transfusions to treat HbE/beta-thalassemia (n=21), where IoIE remained high at 1.51 (Figure 1K). We suggest this reflects the inherent difference in the causes of IE in thalassemia compared to HbSS. In thalassemia there is intrinsic IE due to the imbalance in globin chain synthesis, which will not be significantly changed by blood transfusion. Whereas the IE seen in HbSS may be partly extrinsically induced by the dysfunctional bone marrow microenvironment, shown to improve with recurrent blood transfusion in a recent study of a mouse model\textsuperscript{15}.

The relationship between HbF levels and IE in SCD is complex, demonstrated by the different effects of naturally occurring high HbF levels (reduced IE) and HU (increased IE). This suggests two opposing mechanisms: inherited high HbF levels reduce erythrocyte HbS concentrations and so reduce intramedullary HbS polymerization with improved erythroid survival; conversely, high levels of IE lead to increased selective advantage in favor of cells
expressing more HbF\(^{16}\), resulting in higher circulating HbF levels; this may be one mechanism through which HU mediates its therapeutic increase in HbF, and explain why there is a relative weak correlation between HbF and ineffective erythropoiesis.

In summary, we propose the IoIE as a simple, meaningful and useful measure of ineffective erythropoiesis. We use it to demonstrate that IE exists in patients with HbSS, but not HbSC, and that the genetic ability to synthesize more HbF is associated with less IE. Furthermore, we make the clinically important observation that HU increases IE, whilst blood transfusion reduces IE. Further investigations are required to understand this action of HU in increasing IE in SCD\(^{17}\). HU has a direct effect on cell division which would be expected to increase IE, but may also be acting in other ways, such as increasing stress erythropoiesis in the bone marrow niche of SCD patients. IoIE may be useful to monitor the effects of transfusion and HU in SCD, and to evaluate the effects of novel therapies.
