Publisher's Disclaimer.

E-publishing ahead of print is increasingly important for the rapid dissemination of science.

Haematologica is, therefore, E-publishing PDF files of an early version of manuscripts that have completed a regular peer review and have been accepted for publication.

E-publishing of this PDF file has been approved by the authors.

After having E-published Ahead of Print, manuscripts will then undergo technical and English editing, typesetting, proof correction and be presented for the authors' final approval; the final version of the manuscript will then appear in a regular issue of the journal.

All legal disclaimers that apply to the journal also pertain to this production process.

Hypomethylating agents plus venetoclax *versus* intensive chemotherapy prior to transplant in high-risk acute myeloid leukemia

Aaron D. Goldberg: Consultancy/advisory roles and/or board/advisory committee memberships with Astellas, Bristol Myers Squibb, Molecular Partners, Syndax, Genentech, AbbVie, and Daiichi Sankyo; consultancy with Ikena Oncology; honoraria from Kura Oncology and DAVA Oncology; research funding from Aptose, Pfizer, Celularity, Kura Oncology, Aprea, AbbVie, and AROG.

Maximilian Stahl: Advisory board for Novartis, Kymera, Sierra Oncology, GSK, Rigel, BMS, Sobi and Syndax, Kura; consulted for Boston Consulting, GLG and Dedham group and participated in CME activity for Novartis, Curis Oncology, Haymarket Media and Clinical Care Options and is member of the Medical Safety Monitoring Board for Keros Pharmaceuticals.

Sylvain Garciaz: Consultancy/advisory and/or honoraria from Janssen, Servier, and AbbVie; consultancy from ImCheck Therapeutics, Sanofi, AbbVie, and Bristol Myers Squibb; travel grants from Sanofi and AbbVie.

Letter to the editor

High-risk acute myeloid leukemia (AML) defined by cytogenetics and molecular alterations in the 2022 European-Leukemia-Network (ELN) classification has a poor prognosis (1). Allogeneic stem-cell transplantation (allo-SCT) in first remission is associated with a significant reduction of relapse risk and improved survival compared to intensive chemotherapy (IC) only (2). Older AML patients between 60-74 years of age represent a high-risk population, as they frequently have ELN high-risk AML predicting disease resistance to IC (3). In this age group, IC is associated with low complete remission rates (approximately 40-50%) and poor overall survival (OS) (1,4). Thus, there is a need for new therapeutic strategies aimed at decreasing toxicities and improving efficacy in this population. The less-intensive regimen combining the hypomethylating agent (HMA) azacitidine (AZA) and the BCL-2 inhibitor venetoclax (VEN) has considerably changed the treatment paradigm for older subjects with newly-diagnosed AML (5). Allo-SCT after VEN-AZA appears feasible (6), with emerging evidence of post allo-SCT sustained remission (7). Yet it still remains an open question whether HMA-VEN is equivalent to IC on post-transplant outcomes in high-risk AML patients.

Therefore, we assembled a retrospective cohort of consecutive patients aged 60-74 years newly-diagnosed with ELN-2022 adverse risk AML (1) treated with allo-SCT after prior intensive or less-intensive remission induction therapy. All patients were diagnosed between April 2014 and May 2024 at 3 United-States centers (DFCI, MSKCC, Yale Cancer Center) and 5 European centers (France: IPC-Marseille; CHU-Nice; HCL-Lyon; CHU-Bordeaux; Lithuania: Vilnius University-Hospital Santaros-Klinikos). Less-intensive treatment consisted of standard VEN-HMA including 7 days of AZA 75 mg/m² or 5-10 days of decitabine (DEC) 20 mg/m². IC induction consisted of conventional 7+3 or CPX-351 plus additional treatment with *FLT3*-inhibitors per local standards for *FLT3*-mutated patients. Patients in the IC arm could receive consolidation therapy with Cytarabine per local standards.

Data were collected from patients' electronic medical records. Institutional review boards of all the participating sites approved the study. We used ELN-2022 response

criteria (1). Composite complete remission (cCR) was defined as complete remission (CR) + CR with incomplete count recovery (CRi). Overall response (OR) was defined as cCR + morphologic leukemia-free state (MLFS). Time-to-event outcomes were defined from the date of allo-SCT. OS was defined as the time to death from any cause. RFS was the time to either relapse or death. CIR was defined as the time to relapse, with NRM considered a competing risk. All statistical tests were two-sided and $P < 0.05$ was considered statistically significant. Survival rates were estimated using the Kaplan-Meier method. Log-rank test was used to compare OS and RFS. RI and NRM were compared with Gray's test. Survival analyses were performed using a Cox proportional hazards regression or a Fine-Gray model in competing risks setting. Multivariable regression models included baseline factors present in $>10\%$ of patients and factors significant in univariable analyses ($p < 0.10$).

We included 139 patients with newly-diagnosed adverse-risk AML per ELN-2022 who consecutively underwent allo-SCT after first-line therapy between September 2014 and July 2024 (Supplemental Figure 1). The median age at diagnosis was 66 years (60-74). Eighty-four patients (60%) had received IC as induction therapy, including 64 (76%) with 7+3 and 20 (24%) with CPX-351 (Table 1). Five patients received *FLT3* inhibitors during induction therapy. AMLs treated with HMA-VEN were more likely to harbor monosomal or complex karyotype (54% vs 28%, $P=0.002$), chromosome 5q (del5q, 32% vs 16%, $P=0.032$) and 7q deletions (del7q, 28% vs 9%, $P=0.003$), or chromosome 17p abnormalities (27% vs 6%, $P=0.001$). Twenty-nine patients had *TP53* mutations (20.8%), including 23 (16.5%) with a *TP53m* VAF $>10\%$. HMA-VEN treated patients had *TP53*-mutated AML in 32% vs 13% in the IC group ($P=0.005$).

In the HMA-VEN group, CR, CRi, and MLFS rates were 58.5%, 19%, and 13%, respectively. cCR and OR rates were 77% and 91%. In the IC group, responses were achieved after one ($n = 53$, 83%) or two ($n = 11$, 17%) cycles of induction chemotherapy. CR, CRi, and MLFS rates were 66%, 5%, and 6%, respectively. cCR and OR rates were 71% and 77%. MRD status at time of best response was available for 68/112 patients who achieved OR during induction. In the HMA-VEN group, 22 patients (73%) were MRD⁻, while 8 (27%) were MRD⁺. In the IC group, 24 (63%) were MRD⁻ and 14 (37%) MRD⁺.

Seven patients who achieved response relapsed prior to allo-SCT (all in the IC group). When adding patients who never achieved remission, a total of 31 patients were transplanted with active disease, 5 (9%) in the HMA-VEN group and 26 (31%) in the IC group ($P=0.003$).

With a median follow-up of 52.3 months (95%CI, 44.4-63.7), post allo-SCT OS was 34.4 (95%CI, 16.1-NA) and 28.3 months (95%CI, 14.9-56.3) in the HMA-VEN and IC groups, respectively ($P=0.636$). RFS was 29.2 (95%CI, 14.7-NA) and 21.1 months (95%CI, 10.7-48.7) in the HMA-VEN and IC groups, respectively ($P=0.959$, Figure 1A-B). NRM and CIR were similar between both groups (NRM at 6 and 12 months: 8% and 11% in the HMA-VEN group vs 5% and 18% in the IC group, $P=0.632$; CIR at 6 and 12 months: 11% and 25% in the HMA-VEN group, 13% and 23% in the IC group, $P=0.643$). We evaluated survival for patients in cCR at time of allo-SCT and compared it with patients transplanted without achieving cCR. In the HMA-VEN group, post allo-SCT OS was 38.8 (95%CI, 22.2-NA) vs 6.6 months (95%CI, 2.73-NA) respectively ($P=0.022$). In the IC group, post allo-SCT OS was 48.7 (95%CI, 27.0-NA) vs 12.8 months (8.8-38.7, $P=0.010$). For these patients, outcome was not impacted by induction type ($P=0.55$, Figure 1C-D). MRD status was not predictive of post allo-SCT OS or RFS in univariable analysis (HR=1.39, 95%CI [0.70-2.79], $P=0.347$ and HR=0.81, 95%CI [0.38-1.73], $P=0.583$, respectively).

Multivariable analyses found that induction type (HMA-VEN vs IC) did not impact post allo-SCT OS (HR=0.95, 95%CI=0.54-1.68, $P=0.864$). The only factor associated with better survival was the achievement of cCR at allo-SCT (HR=0.43, 95%CI=0.26-0.69, $P=0.001$). Monosomal karyotype was predictive of worse survival (HR=2.29, 95%CI=1.34-3.92, $P=0.003$, Table 2). Treatment type did not impact RFS (HR=0.49, 95%CI=0.22-1.08, $P=0.08$). Achievement of CR/CRi at allo-SCT was associated with improved RFS (HR=0.29, 95%CI=0.12-0.72, $P=0.0075$) while *N/KRAS* mutation and del7 were associated with worse RFS (HR=2.39, 95%CI=1.10-5.19, $P=0.028$ and HR=3.82, 95%CI 1.68-8.67, $P=0.0014$, respectively, Supplemental table 1).

In exploratory subgroup analyses, patients with AML harboring del5q and *TP53* mutations had better OS with HMA-VEN + allo-SCT compared to IC (HR: 0.31; 95% CI: 0.12 – 0.88; $P=0.027$, and HR: 0.39; 95% CI: 0.16 – 0.98; $P=0.044$, respectively). When analyzing RFS, we found that in patients with monosomal karyotype (HR: 0.31;

95% CI: 0.12 – 0.78; P=0.013), del5q (HR: 0.23; 95% CI: 0.06 – 0.82; P=0.023), del7q (HR: 0.22; 95% CI: 0.06 – 0.82; P=0.024) or 17p.abn (HR: 0.15; 95% CI: 0.03 – 0.94; P=0.042), HMA-VEN before allo-SCT was associated with prolonged survival compared to IC (Supplemental Figure 2).

Allo-SCT after VEN-based treatment is feasible, with low rates of NRM and acceptable OS (6-8). Recent classifications have demonstrated major differences in the prognostic determinants for intensive and less-intensive therapies (9). For example, complex cytogenetics without *TP53* mutations, usually associated with resistance to IC, allow for high response rates with HMA-VEN (10). In multivariable analyses, first-line regimen did not impact OS nor RFS in this cohort of selected patients who underwent allo-SCT. Although no definitive conclusions should be drawn from our subgroup analyses, which are only hypothesis-generating, we found that chromosome 5 and 17p deletions as well as *TP53* mutations favored HMA-VEN compared to IC. Although HMA-VEN has yielded poor results in *TP53*-mutated AML in the VIALE-A cohort (11), most patients were not consolidated with allo-SCT because of age or comorbidities. Interestingly, in a cohort of *TP53*-mutated AML, a recent report found that induction therapy containing VEN was associated with an increased rate of patients proceeding to allo-SCT, most likely owing to reduced toxicity (12).

Our study has several limitations. The present cohort was constructed with consecutive patients who reached allo-SCT after either intensive or less-intensive induction, meaning that patients who did not reach transplant in the study period were not included. Therefore, this study does not report the initial number of patients aged 60-74 who began induction with either HMA-VEN or IC. Induction approach was selected by the physician, possibly influenced by patient and disease characteristics. Our dataset did not include information regarding allo-SCT modalities such as conditioning regimen, donor type, stem-cell source or GVHD prophylaxis, which could all influence post allo-SCT outcome. Data regarding post allo-SCT maintenance therapy was not available. Additionally, a proportion of patients in the IC cohort were treated before VEN approval.

Despite the limitations, this study is in line with recent evidence showing similar outcomes after initial treatment with HMA-VEN or IC in fit patients, in randomized trials

comparing both therapies (13). HMA-VEN may allow higher response rates and reduced toxicity, which in turn might improve survival when compared to IC (7,13,14).

Until sufficient follow-up is reached in these studies, real-world data can provide evidence supporting the use of HMA-VEN as an alternative, less toxic induction strategy for patients with ELN-2022 adverse-risk AML who are intended to proceed to allo-SCT.

*Composite of 7 + 3 and liposomal cytarabine/daunorubicin.

†Therapy-related disease was defined as receipt of chemotherapy and/or radiation for a prior nonmyeloid neoplasm.

‡Cytogenetic analysis was available in 121 of 139 patients (87%) .

§Only mutations present in $\geq 5\%$ of patients included.

VHRcm (Very High Risk cytogenetic and molecular alterations) : complex karyotype, monosomal karyotype, MECOM rearrangement and/or TP53 mutation

Variables without "Missing data" specification had no missing data, i.e, statistical analyses were performed on N=139 patients, N=55 in the HMA-VEN cohort and N=84 in the Intensive chemotherapy cohort

Table 2. Univariable and multivariable analyses for OS

Overall Survival						
Variables	Univariable analyses			Multivariable analysis †		
	HR	95% CI	P	HR	95% CI	P
HMA-VEN vs IC	1.13	0.7-1.84	0.64	0.95	0.54-1.68	0.864
Age ≥ 70	0.86	0.5-1.46	0.57	-		
Prior Myeloid malignancies	1.46	0.90-2.35	0.12	-		
Therapy related	1.2	0.67-2.15	0.54	-		
Response Status prior to allo-SCT (cCR vs Active Disease)	0.47	0.30-0.75	0.001	0.43	0.26-0.69	0.001
Monosomal Karyotype	2.15	1.32-3.50	0.002	2.29	1.34-3.92	0.003
Complex Karyotype	1.64	1.03-2.62	0.04	-

† Final multivariable model was reached after using a stepwise regression to minimize model complexity

Figure 1: Overall survival and Relapse-free survival in patients treated with allo-SCT after prior induction with hypomethylating agents plus venetoclax (HMA-VEN) or intensive chemotherapy (IC). Figure A compares post allo-SCT OS for patients treated with either HMA-VEN or IC. Figure B compares RFS for patients treated with either HMA-VEN or IC. Figure C compares patients in complete response (CR) and CR with incomplete hematological recovery (CRi) with patients in morphologic leukemia free-state (MLFS) and progressive disease (PD) for both treatment type. Figure D compares patients in CR-CRi with patients in MLFS after excluding patients treated by allo-SCT with an active disease, for both treatment type.
