## Online Supplementary Appendix

Minimal residual disease-derived risk group classification and final stratification
Patients were defined as having standard-risk minimal residual disease (MRD-SR) if no MRD was detected on both day 33 (TP1) and day 78 (TP2), using at least two molecular markers with sensitivity of $\leq 10^{4.4}$. If MRD levels differed between the two markers, the highest MRD level was chosen for the final MRD assessment. Patients were considered MRD intermediate risk (MRD-IR) when MRD was positive at one or both time points but at a level of $<10^{-3}$ at TP2 with at least two markers.

Patients with MRD $\geq 10^{3}$ at TP2 were defined MRD high risk (MRD-HR). Patients with a prednisone-poor response (i.e. with $\geq 1000$ leukemic blasts/ $\mu \mathrm{L}$ in the peripheral blood on day 8) or failure to achieve remission (i.e. with $\geq 5 \%$ leukemic blasts in the bone marrow on day 33, or persistent extramedullary disease) after induction phase IA (induction failure) or positivity for MLL/AF4 fusion transcript were treated in the high-risk arm independently of their MRD results. If MRD evaluation was not available, patients were assigned to the intermediate-risk group or, based on clinical parameters, to the high-risk group; these patients are not including in this study.

Online Supplementary Figure S2. Representative dot plots exemplifying the flow cytometric analysis and gating strategy. This day 15 bone marrow sample from a patient with BCP-ALL was divided, NC were prepared for four-color analysis ( 3 tubes; A and B), and MNC were prepared for seven-color assessment (1 tube; C and D). Events were acquired on a BD FACSCalibur ${ }^{\text {TM }}$ (four-color assay) and on a BD LSRIITM (seven-color assay). Data sets were analyzed using FACSDiva ${ }^{\top M}$ software. First, gating was performed on cellular events positive with the cell-permeable nuclear dye SYTO®16 or -41 in order to include only relevant events in the quantitative assessment. Subsequently, B cells were identified in the data sets from the tubes containing the SYTO ${ }^{\circledR}$ dye (see Online Supplementary Table S1) by plotting CD19 against SSC, and potential leukemic CD19+ cells (red) based on expression of the immaturity marker CD10 (normal B cells are painted green). In dual-color plots the supposedly leukemic cells were checked for leukemia-associated phenotypic aberrations in order to define MRD. In this case, asynchronous expression patterns distinct from regular differentiation as well as over-expression of CD58 were found. Finally, back-gating of MRD-cells in the FSC/SSC plot was used to exclude events from further calculations which appeared in the debris region. Note the good quantitative concordance of MRD estimates as well as the largely similar staining patterns between both set-ups, despite the use of different fluorochrome conjugates and different numbers of acquired cells (A and $B: \leq 300000$ cells; $C$ and $D: \geq 500000$ cells per tube).

Online Supplementary Table S1. Antibody combinations used to detect leukemia-associated immunophenotypes at diagnosis and during follow-up in patients with either B-cell precursor (BCP)ALL or T-ALL.
